Abstract

Increasing amounts of MoO₃ were added to SiO₂-B₂O₃-Na₂O-CaO-Al₂O₃ glasses in order to trap molybdenum as powellite (nominally CaMoO₄). Different heat treatments were performed to study their influences on powellite crystallization by X-ray diffraction and EPR. The glass compositions studied in this work lead to glass-ceramics rich in CaMoO₄, up to [MoO₃] = 5 mol% no poorly durable Na₂MoO₄ phase was identified by XRD. Trivalent actinides surrogates (Gd³⁺) were observed to incorporate into CaMoO₄ crystals.

Keywords: molybdenum, glass-ceramic, powellite, XRD, EPR

1. Introduction

Spent fuel from GCR (Gas Cooled Reactors), mainly worked in France and U.K. during the second part of the 20th century is highly concentrated in molybdenum. During vitrification processes, Mo-rich glasses can lead to the separation of a poorly durable phase (called “yellow phase”) containing radioactive elements like ¹³⁷Cs [1]. Indeed, in glasses prepared under neutral or oxidizing atmospheres, molybdenum appears mainly as Mo⁶⁺ with a low solubility (~1 mol%) and crystallize in alkali or alkaline-earth molybdates during melt cooling and heat treatments. Crystallization of the poorly durable phase Na₂MoO₄ must be avoided to keep a low leachability of the immobilization glass matrices.

Glass-ceramics are known to exhibit improved properties with respect to glasses as mechanical and thermal properties [2]. Besides glass-ceramics are easier to process than ceramics since no high pressures or extremely high temperatures are needed. Therefore, new glass ceramics formulations [3,4] were studied to trap up to 12 wt% of molybdenum as powellite CaMoO₄ which is a stable phase in vitreous medium.

In this work, we synthesized calcium enriched aluminoborosilicate glasses to study the CaMoO₄ formation and to obtain a simplified model for powellite-rich glass-ceramics. Heat treatments were performed to control the content and the size of crystallites and the structural changes were studied by X-ray diffraction (XRD) and electron paramagnetic resonance (EPR) measurements.

2. Experimental methods

For this study, we prepared glasses in the system: $\text{SiO}_2\text{-B}_2\text{O}_3\text{-Na}_2\text{O-CaO-Al}_2\text{O}_3$. A small quantity of Gd_2O_3 (0.15 mol%) was added to all glasses to study the speciation of rare earth elements between the glassy and crystalline phases. For that purpose, Gd^{3+} was used as a spectroscopic probe for EPR measurements. Indeed, EPR spectroscopy is a quantitative tool for analyzing ion speciation and Gd^{3+} ion EPR spectra are known in glasses [5,7].

Two series were prepared where $x=0.5, 2.5, 5, 7$ mol% corresponds to MoO_3 content:

- (i) M1x with MoO_3 and CaO introduced in stoichiometric proportions $(0.9985-2x/100)(65.04 \text{ SiO}_2 - 17.22 \text{ B}_2\text{O}_3 - 13.67 \text{ Na}_2\text{O} - 4.14 \text{ Al}_2\text{O}_3) - x \text{ CaO} - x \text{ MoO}_3 - 0.15 \text{ Gd}_2\text{O}_3$ (in mol%).
- (ii) M2x with Ca introduced in excess $(0.9985-2x/100)(61.16 \text{ SiO}_2 - 16.28 \text{ B}_2\text{O}_3 - 12.85 \text{ Na}_2\text{O} - 3.88 \text{ Al}_2\text{O}_3 - 5.82\text{CaO}) - x \text{ CaO} - x \text{ MoO}_3 - 0.15 \text{ Gd}_2\text{O}_3$ (in mol%). For all M2x glasses we have $[\text{CaCO}_3] > [\text{MoO}_3] + [\text{Al}_2\text{O}_3]$ so that more Ca^{2+} ions are available to crystallize into powellite.

Parent glasses were prepared by mixing desired amount of reagent grade SiO_2 , H_3BO_3 , Na_2CO_3 , Al_2O_3 , CaCO_3 , MoO_3 and Gd_2O_3 . Each batch (~30 g) was melt at 1500°C for 3 h and ground before remelting (1500°C for 2 h) for homogeneity. During the first melting, a plateau at 700°C during 4 hours is necessary for decarbonation of Na_2CO_3 and CaCO_3 . Samples are quenched onto a copper plate or into water and are annealed at 500°C for 2 h to relieve internal stresses. Chemical analysis by EDX (energy dispersive X-ray analysis) of glasses showed that the final Na content is about 40 % lower after the melting process, other elements contents seemed to be unchanged (boron content was not measured).

Ceramics were elaborated with two chemical compositions: pure powellite CaMoO_4 and powellite containing 0.15 mol% of Gd_2O_3 (mentioned later as $\text{CaMoO}_4\text{-Gd}$). Appropriate amounts of reagents were grounded and pellets were obtained with a mechanical press. Ceramics were then sintered at 1150°C for 12 h under air.

Two different crystallization methods were investigated to control size and concentration of powellite.

- (i) The first method consists of a nucleation stage at T_n and a crystal growth stage at T_c on annealed parent glasses. Samples were treated at $T_n = 650^\circ\text{C}$ or $T_n = 950^\circ\text{C}$ during 2 h and then transferred to a preheated furnace at $T_c = 1050^\circ\text{C}$ or 1100°C for 2 h and 20 h.

- (ii) The second method consists of a rapid cooling (0.5 h) from 1500°C following the 2nd melting to a crystal growth stage at $T_c=1100^\circ\text{C}$ during 4h or 22h. The samples were then quenched to room temperature in water or in air.

All samples were reduced into powder ($< 40\mu\text{m}$) and studied by (XRD). The diffraction data were collected at room temperature on a Panalytical (Philips) diffractometer in the Bragg-Brentano geometry with a Cu anti-cathode: $K_{\alpha 1}$, $K_{\alpha 2}$ ($\lambda = 1.54560 \text{ \AA}$ and $\lambda = 1.54439 \text{ \AA}$, 40 kV, 40 mA) and a linear detector. The angular range $15^\circ - 60^\circ$ was scanned in 0.02° steps with a minimum counting time of 90 s/step. Particular attention was paid to probe the same volume of powder for all samples during XRD measurements. EPR measurements were effected at room temperature on a X band ($\nu = 9.86 \text{ GHz}$) EMX Bruker EPR spectrometer using a 100 kHz field modulation, 3 Gauss of amplitude modulation. Microwave powers (MP) between 1 and 50 mW were used for studying Gd^{3+} and Mo^{5+} ions environments and for analyzing their microwave saturation properties.

3. Results and discussion

Figure 1 shows the XRD patterns of samples M1x and M2x with increasing Mo concentration. The broad line around $22^\circ 2\theta$ is attributed to the WAXS (Wide Angle X-ray Scattering) signal of the amorphous aluminoborosilicate phase. Powellite is the only crystalline phase observed in the various XRD patterns of glass ceramics with $[\text{MoO}_3] \leq 5 \text{ mol\%}$. For the highest Mo concentration (7 mol%), samples are heterogeneous. However M27 is more homogeneous than M17 since there are only small inclusions in the M27 bulk compared to a phase completely separated from the M17 bulk. Moreover a thin yellow layer is observed on the M17 sample after quenching on a copper plate. The XRD patterns on figure 1 (g) and (h) show that the separated phase and the inclusions are composed of CaMoO_4 (JCPDS 01-077-2238), Na_2MoO_4 (JCPDS 01-073-1797) and $\text{Na}_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$ (JCPDS 01-070-1710). The appearance of a $\text{Na}_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$ phase could be due to hydration of the Na_2MoO_4 phase during samples storage after the synthesis. In addition, the relative proportion of alkali molybdates in the separated phase of M17 sample is qualitatively higher than in the inclusions of the M27 sample. In this work, the calcium content in the parent glass seems to be an important parameter to control samples homogeneity and limit alkali molybdates precipitation for high $[\text{MoO}_3]$ content. From now on we will focus on the M2x series.

The EPR spectra for the M2x series, illustrated in figure 2, show different well-known lines typical for Gd^{3+} and Mo^{5+} ions in glass. For $[MoO_3] \geq 2.5$ mol% a complex signal composed of various lines is observed. The lines at $g \sim 2.0$, $g \sim 2.8$ and $g \sim 6.0$ correspond to the so called “U” spectrum and are attributed to Gd^{3+} in network modifier position ($Gd^{3+}_{[n.m]}$) [6]. The signal at $g=4.6$ is attributed to Gd^{3+} characterized by high crystalline field acting as network former ($Gd^{3+}_{[n.f]}$) [6]. The broad resonance can be ascribed to magnetic oxide clusters of Gd^{3+} ions, linked through the oxygen bridges [7]. The last EPR line at $g=1.91$ could be attributed to Mo^{5+} diluted in the glassy phase [8, 9, 10]. The increase of MoO_3 content and therefore the powellite phase formation lead to different changes on the M2x samples EPR spectra. The first is a decrease of $Gd^{3+}_{[n.f]}/Gd^{3+}_{[n.m]}$ ratio (see inset in figure 2). We approximated this ratio by the ratio of the intensity of the line at $g = 4.6$ over the intensity of the line at $g = 6$ since the lines at $g = 2$ and 2.8 are superimposed on other EPR signals. The second change is the increase of the Mo^{5+} line with MoO_3 content in glass as reported in [9]. The last change is the appearance with the Mo doping level of a new complex EPR component which is described in details below.

Figure 3 shows the EPR spectra of the $CaMoO_4$ ceramics with and without gadolinium. The only EPR lines in common between the two ceramics are the six lines centered at $g = 2$ attributed to diluted Mn^{2+} ions [11] and correlated to the presence of this impurity in the reagents used for the synthesis. As a consequence, the other EPR lines on the $CaMoO_4$ -Gd spectra could be associated to Gd^{3+} ions incorporated into the powellite crystalline phase. The circled lines on the figure 2 are all observed on the $CaMoO_4$ -Gd EPR spectrum. Moreover, microwave saturation properties of the Gd^{3+} EPR spectrum suggest that this ion is inserted in several sites in the powellite structure, further studies will be made to determine the nature of the different Gd^{3+} ion sites in the powellite structure.

Two different heat treatments were performed on samples to change the microstructure. At the macroscopic scale, a sharp difference between the two treatments is visible by eye. Indeed, for the M225 samples no differences are seen for samples heat treated by nucleation (2 h) and crystal growth (20 h) at $1100^\circ C$, on the contrary powellite needles (see figure 4,d) are clearly visible in the M225 heat treated at $1100^\circ C$ for the crystal growth stage during 22 h. After various heat treatments, only powellite is observed by XRD in addition to the aluminoborosilicate glass for $[MoO_3] \leq 5$ mol%. Nevertheless, the gaussian width does not evolve as expected since the FWHM (full width at half maximum) does not decrease with heat treatments duration. We have therefore no increase of the coherent domains size of powellite crystals during the growth stage. Moreover, no increase in powellite concentration

was detected by XRD, which could be due to an inappropriate nucleation temperature. The EPR study reveals a decrease of Mo^{5+} ions (see figure 4,c) in glass with heat treatment duration for all samples. This result could be associated to a change in redox couple of the elements during the nucleation and crystal growth stage. No significant change in the EPR lines associated with Gd^{3+} incorporated into the powellite phase is observed. The $\text{Gd}^{3+}_{[\text{n.f.}]}/\text{Gd}^{3+}_{[\text{n.m}]}$ ratio changes with heat treatments but no global trends with durations or temperatures were found. In addition, this work shows that Gd^{3+} is a good EPR probe for studying the speciation of this ion between the different sites of the glassy and crystalline phases as a function of synthesis and heat treatments conditions.

The synthesis parameters used in this work have shown that we can obtain a two phase system of glass-ceramics. The fact that only CaMoO_4 is detected by XRD in samples for $[\text{MoO}_3] \leq 5$ mol% could be due to the high percentage of B_2O_3 [9,12] combined with the addition of Al_2O_3 introduced in the glass composition [13]. In that case, the sodium acts as a charge compensator of BO_4^- and AlO_4^- units and is not available for the crystallization in alkali molybdates. EPR spectroscopy has shown the presence of different paramagnetic species like Mo^{5+} ($S = 1/2$) in the glassy phase and Gd^{3+} ($S=7/2$) in the powellite phase. The decrease of $\text{Gd}^{3+}_{[\text{n.f.}]}/\text{Gd}^{3+}_{[\text{n.m}]}$ ratio in the glassy phase is associated to the powellite formation. This result could therefore show that Gd^{3+} ions in network former positions enter mainly in the powellite phase. D. Caurant et al. [9] proposed that Mo^{6+} ions are in depolymerized regions of the glass and could be precursors of the nucleation stage. According to this work, the decrease of $\text{Gd}^{3+}_{[\text{n.f.]}$ relative concentration could show the presence of these ions in the vicinity of the depolymerized parts of the glass. X-ray results did not revealed a change in size or concentration of powellite, therefore analysis with imaging techniques like SEM (scanning electron microscope) are in progress and have shown to be a good way to study the powellite size evolution.

5. Conclusion

The study of two series of glass-ceramics belonging to the system $\text{SiO}_2\text{-B}_2\text{O}_3\text{-Na}_2\text{O-CaO-Al}_2\text{O}_3\text{-MoO}_3$ with increasing MoO_3 content highlights two main points. The considered synthesis protocol leads to glass-ceramics containing powellite in a glassy matrix under various heat treatments. No poorly durable Na_2MoO_4 phase was detected by XRD for $[\text{MoO}_3] \leq 5$ mol%. The XRD study also showed that an increase of CaO content may favor the CaMoO_4 crystallization. EPR measurements revealed a complex spectrum only observed in

glass-ceramics containing powellite, which could be associated to Gd^{3+} ions incorporated into the crystalline phase.
